S_N1 Displacement At sp³ Centers

from chapter(s)	in the recommended t	ext

A. Introduction

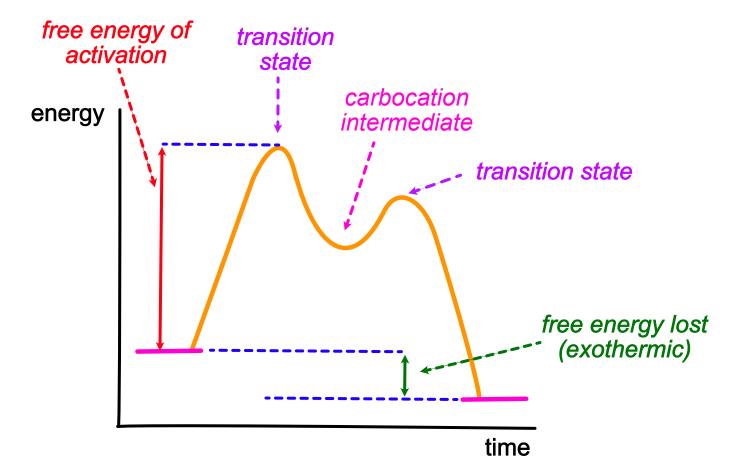

B. Fundamentals

It takes *more / less* energy to separate most neutral molecules into cation-anion pairs than it does to combine cations with anions because of electrostatic forces.

Assuming this is true for the following reaction, formation of the carbocation requires energy from the system. Even so, carbocations *can* be isolated so they *are* stable intermediates.

movement of electrons from cyanide to the empty p-orbital of the carbocation.

Reactions like this are usually *more* favorable when a tertiary (3°) carbocation is formed since these tend to be *more* stable than secondary (2°) or primary (1°) ones.

Dissociation of chloride in this reaction hence the first transition state is *higher* energy

The carbon of the carbocation intermediate is sp^2 hybridized and groups are arranged around in in a triangular shape.

Approach of nucleophiles, like cyanide, on that carbocation will involve the same energies for the pro-R and pro-S faces. Consequently, if the starting material is one pure enantiomer then the product will have 0 % enantiomeric excess

Nucleophiles are involved in the dissociative step of S_N1 reactions so their reaction rates are proportional to *only the substrate* concentrations.

Represent the rate of S_N1 reactions using the symbol k to represent the *rate* constant,

rate = k[substrate]

C. Charges On Nucleophiles And Leaving Groups

Nucleophiles

$$N_3^-$$
 + MeI = MeN₃ + I⁻ 2 AcO⁻ + CI = AcO OAc + 2 CI

$$CI$$
 + S = S + CI BnBr + I = BnI + Br

$$Et_3N + MeI = Et_3N + MeI = Et_3N + CI$$

$$2 Te + CI$$

$$CI = Te + CI$$

$$CI$$
 + S = S + CI BnBr + PPh₃ = BnPPh₃ + Br

$$Et_2NH + 1 Mel = Et_2NMe + HI$$
 Ph $SH + CI$ $=$ Ph $S + HCI$

$$Ph$$
 Cl + HO = Ph O + HCl Me_3O^+ + I^- = Me_2O + Mel

Leaving Groups

$$CI$$
 + $N=N+=N^-$ = N_3 + CI^- MeI + NaSCN = MeSCN + NaI

$$N^{+}Ph_{3}$$
 + NC^{-} = $N^{+}Ph_{3}$ + $N^{+}Ph_{3}$ + $N^{-}Ph_{3}$ + $N^{-}Ph_{3}$

$$LiO \longrightarrow S^{+} CI^{-} = O \longrightarrow + LiCI$$

(intramolecular)

$$Ph_3P^+Me\ Cl^- + NaSEt = PPh_3 + MeSEt + NaCl$$

D. $S_N 1$ Slow Formation Of Carbocations

Key Steps

Substitution describes reactions in which one group *replaces another*.

S_N1 stands for substitution by a nucleophile *with first order kinetics*.

carbocation and bromide

benzyl carbocation and -OMs

formation of a carbocation is the rate limiting step.

tosylate

allyl carbocation and O⁻Ts

hydrogen phosphate

allyl carbocation and hydrogen phosphate

an allyl carbocation and hydrogen phosphate

carbocation and hydroxide

carbocation and water

Water is a much better leaving group than hydroxide pathway on the *right* is more favorable the one on the *left* does not proceed at all.

Some poor leaving groups can be converted into better ones by protonating them: true

only protonation of O¹ is stabilized by resonance from the other oxygen.

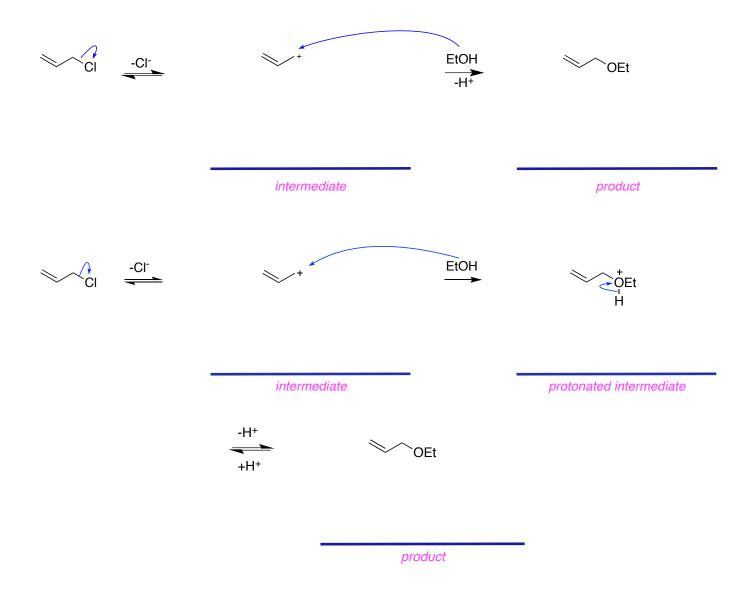

E. S_N1 Fast Combination Of Cations With Nucleophiles

Carbocations *can* combine with negatively charged nucleophiles to produce neutral molecules.

When carbocations combine with neutral nucleophiles they form cations

the products will be *racemic*, because the intermediate, *sp*²-hybridized carbocations, are *flat*

intermediate product

S_N1 reaction of *tert*-butyl chloride with water involves *two* intermediates.

S_N1 reaction of *tert*-butyl bromide with acetate (MeCO₂-) involves *one* intermediates.

S_N1 reaction of bromide with allyl chloride involves *one* intermediates.

carbocation intermediate

product and HCI

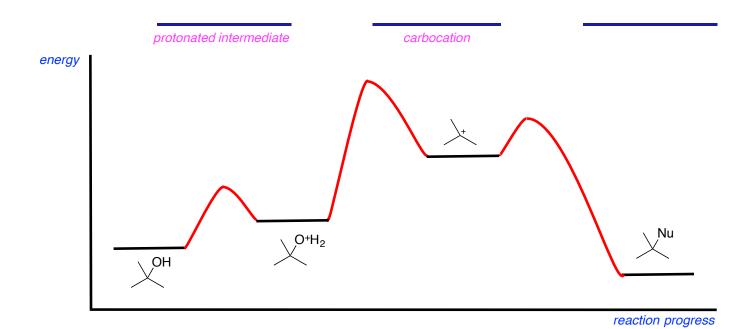

а

carbocation intermediate

protonated amine

F. S_N1 Kinetics

	[tp., O. 1]		/ ttp. O. II
rate is proportional to	[ˈBuOH]	rate =	k [^t BuOH]

the rate of the reaction above *is* proportional to the concentration

triphenylmethyl chloride with sodium cyanide proceeds *at the same rate* the if the concentration of the cyanide salt is doubled

G. Carbocation Stabilities Govern S_N1 Reaction Rates

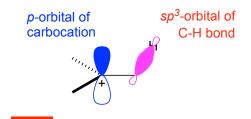

Rates of $S_N 1$ reactions tend to *increase* with stabilities of carbocation intermediates.

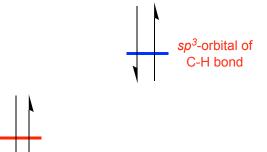

most stable least stable

$$\bigvee$$
 Br \bigvee Br \bigvee Br

fastest slowest

p-orbital of carbocation

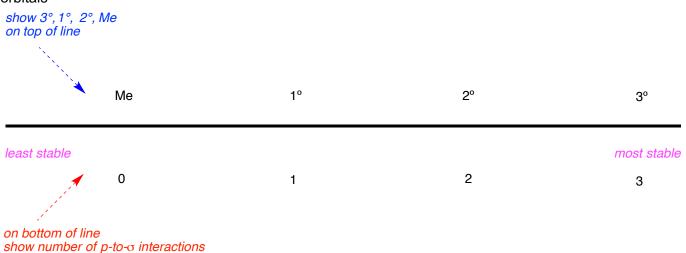

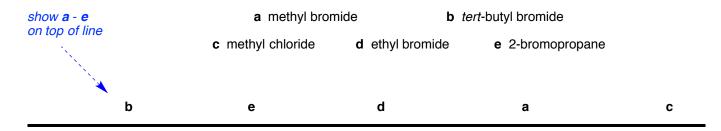

There are 3 times more of these interactions in the ^tBu cation than in Me⁺.

In Et⁺ the sp³ orbitals of the methyl group are tilted a bit away from the empty p-orbital of the cation, thus the overlap, and therefore the stabilization, is *less* than a situation in which the orbitals were completely parallel.

system overall is *greater* than that from hyperconjugation in Et⁺. Allyl cations are *more* stable than many other primary carbocations.

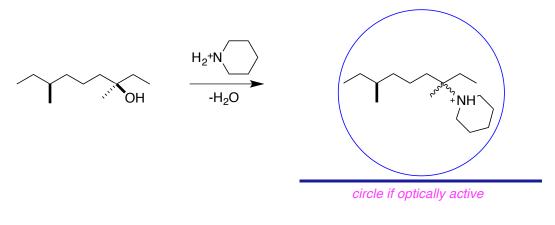

secondary molecular orbital interactions between an *empty* p-orbital and appropriately aligned C-H σorbitals

fastest slowest

H. Relative Stereochemistry In $S_N \mathbf{1}$

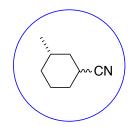

circle if optically active

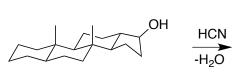

$$\operatorname{Bu} \longrightarrow \operatorname{HCN} \longrightarrow \operatorname{H2O}$$

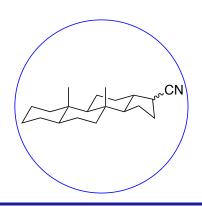

circle if optically active

$$\longrightarrow$$
 HCN \longrightarrow -H₂O

circle if optically active

circle if optically active
